Preface: International Conference on Biology and Applied Science (ICOBAS)

International Conference on Biology and Applied Science (ICOBAS) 2019 is a well-established scientific meeting that provides a scientific forum to contribute to biodiversity conservation and environmental protection especially in this 4 industrial revolution era. The conference has taken places at Sahid Montana 2 Hotel, 13-14 March 2019, and organized by the collaboration between Department of Biology, Faculty of Science and Technology, State Islamic University of Malang, Indonesia; Mukaishima Marine Laboratory, Graduate School of Science, Hiroshima University Japan; Faculty of Life and Environmental Science, Prefectural University of Hiroshima (PUH) Japan; Department of Biology, Chulalongkorn University, Thailand and Society for Biology Lecturer of Islamic Universities of Indonesia.

The objectives of the conference are to provide a scientific forum to contribute to biodiversity conservation and environmental protection, especially in this 4 industrial revolution era. In this forum, the scientist shared their knowledge and explored the opportunities for international collaboration from a range of disciplines in order to sustain our biosphere. The scopes of the conference include, but not limited to, the following topic areas: botany, zoology, ecology, biotechnology, biodiversity conservation, environmental protection and policy and biology education.

This conference not only included keynote and invited speakers, but also oral and poster presentation. As well, some satellite activities such as the use of microscope training, herpetofauna workshop were also performed in accordance with this conference. Even this conference is the first conference on Biology and Applied Science, but the number of attendants reached 260 researchers including several attendants from foreign countries, such as Thailand, Japan, and France.

These proceedings contain articles that were accepted for publication through the double review process. A total of 163 papers have been accepted for publication in this proceeding. Finally, we would like to express our deep gratitude to all committee members, keynote and invited speakers, anonymous reviewers, authors, sponsor and all who have contributed for the success of ICOBAS 2019.

Abstract. The aims of this research are to describe the effect of adding organic biomass (which are Azolla, straw and organic fertilizer) to the diversity of detritus arthropods and natural enemies, and to analyze the dissimilarity of habitat in each treatment's field and to define the improvement of agro-ecosystem toward treatments. Fieldwork was conducted in Watugede of Singosari, Malang regency. Four areas of the rice field were chosen from an overlay as the site for each treatment. We used both direct sampling and baiting to collect arthropods. For baiting, pitfall trap was used. For direct sampling, we take soil samples then placed in berlesse-tullgren funnel. Data converted to α and β diversity. Analysis of variance was used to ensure any improvement between habitats. The results show that adding certain biomass at the beginning of the agricultural system will enhance the population and diversity of detritus arthropods. It's also enhancing natural enemy's diversity. Adding organic fertilizer has the biggest impact. There was an improvement of habitat in the treatments fields. The improvement comes from the higher possibility to gain ecological services. Adding biomass also enhances agro-ecosystem health according to the occurrence of richness-dominance covariance.

INTRODUCTION

Maintaining biodiversity is important to gain ecological services [1]. Ecological services in agricultural production system consist of pest control, pollination and nutrient cycle. Diversity contributes to the efficient use of natural resources [1]. In the other hand, reduced diversity in agro-ecosystem caused an increasing need for human intervention. It means that the decreasing of biodiversity caused a huge dependency on external input and less efficient [1].

In many cases, the simplicity of arthropod's diversity in an agro-ecosystem tends to trigger pest outbreak [2]. Monoculture allows the greater chance for the development of invasive species [3]. It has happened frequently since the policy of agriculture intensification applied. Even now, the more intense pesticide usage is needed, in order to anticipate the occurrence of pest resistance [4]. The intensive pest control effort has been in-effective in minimizing crop loss [5].

Monoculture is recommended by government policy in rice agricultural system. As the main food in Indonesia, plant rotation strategy has been discouraged. Then, there is poor diversity either over space or time. The simplicity of agro-ecosystem leads to a lack of ecological services. It makes rice agricultural system less efficient. It will depend on more and more need for external input [6].

Good quality of agro-ecosystem could be adaptive from any challenge including pest problem. Indicator of a good quality agro-ecosystem is the higher diversity and the lower chemical input [7]. The first step to gain a good quality of agro-ecosystem is choosing farming methods that less favourable for pest invasion. The second is emphasizing the use of local resources and minimizing external inputs such as inorganic fertilizer and chemical

International Conference on Biology and Applied Science (ICOBAS) AIP Conf. Proc. 2120, 040010-1–040010-9; https://doi.org/10.1063/1.5115648 Published by AIP Publishing. 978-0-7354-1860-8/\$30.00 pesticides. Also, the third step is enriching the soil by composting, mulching or adding animal manure [8]. Enrich the soil with organic matter will generate microhabitat supporting the life of various soil organism [9].

Since there's limited option to increase diversity in a rice field, enhancing functional diversity from organic soil management aspect is the most reasonable way [1]. It could be done by adding organic matter into the field. Application of organic matter or biomass will manipulate the detritus food web. As it will provide the energy source for the detritus species and so increasing diversity. The increasing of detritus diversity will boost the diversity of generalist predator [10]. Detritus will subsidize food for predator especially at the earlier of rice stage [11]. So, diversity increases naturally based on nutrition flow from the bottom to the top of the food web.

The enhancement of detritus species richness will also amplify its role on soil physic regulation. Detritus activity will improve soil porosity and so provide aeration. The activities also boost the mixing between the organic and mineral fraction of the soil and make mineral available for the plant. Even its feces contribute to humus formation, which physically stabilizes the soil and increase its capacity to store nutrient [12].

Providing any cultural option in order to enhance the detritus population in the soil is important. The option must be based on resources availability and also economically reasonable [13]. Straw is a potential local resource. It's available in every agricultural cycle. In fact, local farmers used to burn the straw. This treatment is contraproductive towards soil arthropods diversity [14]. The next local resource is *Azolla pinata*, a plant species which spread rapidly in the wet rice field. Also, its debris has a high nitrogen compound. The other option is animal manure fermented into organic fertilizer. It provides not only rich nutrient but at the same time, it will fix the soil physic.

The effect of three kinds of biomass added to the occurrence of detritus and the natural enemy was identified. It's focusing to see if any changes in arthropods diversity. Enriching the soil will make a favorable environment for detritus organism. Since detritus play the role as a substitution energy source for predator's [11], it's interesting to figure out the effect on population and diversity of predatory species. The study of diversity effect on the preparation of ecological services in agro-ecosystem also presented. Hopefully, it will encourage the application of detritus conservation at farmer's level.

The objectives of the research are to define (1) Effect of adding certain biomass (Azolla, straw and organic fertilizer) to detritus and natural enemies diversity, (2) dissimilarity of habitat toward each treatment and (3) the improvement of agro-ecosystem in treatment field compared by farmer's field.

EXPERIMENTAL DETAILS

Study Sites

Fieldwork was conducted in rice field overlay in Watugede of Singosari district, Malang regency. This overlay was 58 acres at 450 m above sea level. The research was done in the rainy season in January until April 2016. Four areas of rice fields are chosen from an overlay as the site for each treatment. Each site has a similar size, range from 130 m² up to 150 m². Each site was disconnected in water irrigation. It's also separated each other, either by a pathway or another field area.

Biomass Application

Straw applied shortly after harvesting process. It's already chopped by harvest machine then spread in the whole treatment area. All straw from the area itself was used. Azolla added after the first tillage. Two-weeks period is taken before the second tillage so Azolla could spread over the field. Even though some population will be destructed as long as the second tillage activities, but some more still remain in the field. For the early infestation, there was 5 kg Azolla starter applied.

The next treatment is the application of organic fertilizer for an amount of 200 kg. It also applied after the first tillage. All the treatments field named as + Azolla +Straw and +OF (organic fertilizer). All of it will be compares to non-treatment fields named as farmer's way.

Agricultural Techniques

All the techniques used by local farmer applied in the treatment field, including choosing varieties, day-old transplanting, watering and fertilizing. The pesticide's application is avoided to maximize data of arthropods population.

Sample Collection and Identification

We used both direct sampling and baiting to collect arthropods. For baiting, pitfall trap was used. Pitfall trap placed in five plots on every site. The plots are 30 cm \times 30 cm area in the field takes along the diagonal line across the site. Pitfall traps was a 15 cm in diameter and 20 cm height plastic's tube. Almost 1/3 of the tube filled with soap solution as arthropod's trap. There was no water intake to the field at the day the pitfall placed. The trap is placed 24 hours before it will be taken for observation.

For direct sampling, five plots $(30 \times 30 \text{ cm})$ were taken randomly at least 5m from the edge in order to reduce edge effects. In each plot, there are three sub-plots where the soil sample is taken with soil corer (15 cm depth and 10 cm in diameter). The three soil samples represent 1 plot placed in berlesse tullgren funnel for 2 ×24 h in 15-watt bulb lamp.

Sampling was begun at 7 days after transplanting (DAT) in two-weeks intervals. During plant session, there were 8 observations. All specimens were stored in 70% ethanol and were identified to morpho-species using a stereo microscope and using an introduction to the study of the insect [15] as a guidance in identification.

Data Analysis

To understand whether any change in agro-ecosystem toward biomass added, we used α and β diversity approach. Diversity within habitat measurement consists of the heterogeneity index by Shannon-wiener, index of dominance by Simpson, species richness by Margalef and evenness from Shannon. To ensure any improvement between habitats, analysis of variance (ANOVA) was used and further tested by the least significance differences (LSD). Meanwhile, in describing β diversity, Whittaker formula was chosen. Dominance shifts analysis declared by Magurran [16] was used as an Agro-ecosystem health assessment's method. All data analysis was performed using SPSS 20.

RESULT AND DISCUSSION

Abundance of Arthropods

A total of 4,518 individuals were identified as belonging to 89 morpho-species of arthropods in 6 class-es, 10 orders, and 47 families. All individuals collected then determined each of its roles, whether if it's herbivore, detritus or predator/parasitoid. The list of families and species of arthropods is shown in Table 1.

The most suitable habitat for the abundance of detrivore family is in +OF field. Coleopteran has the highest number of family. The six families found are Carabidae, Curculionidae, Hydrophilidae, Staphylinidae , and Tenebrionidae. All the families were known as debris feeder. Meanwhile, in the predator sides, +O.F. also got the most number of families. The Coleopteran, Hemipteran, and Araneae share the same number of family. Coleopteran order consists of Carabicae, Coccinellidae, Scidmaenidae and Staphylinidae families. Families of Hemipteran order are Geriidae, Mesoviilidae, Miridae, and Veliidae. The Araneae order contains families like Araneidae, Lyniphiidae, Oxyopidae, Salticidae and Tetragnathidae. The most common parasitoid is from Hymenopteran order. The highest number of families identified in +Straw. Nine families are identified as Braconidae, Bethylidae, Chalcidae, Elasmidae, Ichneumonidae, Sceleonidae, Trichogrammatidae, and Vespiidae.

Total individual detritus species collected from all tools vary from 634 in farmer's way to 985 in +Azolla (Fig. 1). It looks like biomass could enhance the detritus population. The organic matter had boosted detritus population [10]. Meanwhile, there's no obvious evidence in the predator side. Despite showing the higher number of predator compares to farmer field, +Azolla becomes the lowest.

There was a huge population of the parasitoid in farmer's field mostly contains *Opius* sp., *Cotesia* sp. and *Goniozus* sp. It found mostly in 7 and 35 DAT, or during the vegetative phase of the plant. It happened again in 77

DAT during the generative phase (Fig. 2). *Cotesia* sp. and *Goniozus* sp. were known as parasitoids of rice leaf-roller (*Cnapalocrosis medinalis*), meanwhile, *Opius* sp. plays a role as rice flies (*Orseolia oryzae*) larvae parasitoid.

TABLE 1. The taxa of detritus and natural enemies found in each treatment field

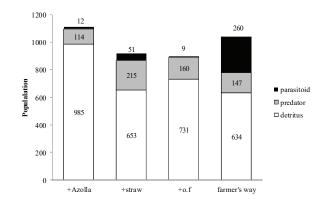

FIGURE 1. Comparison of Total Individuals of Detritus, Predator, and Parasitoid in Each Field

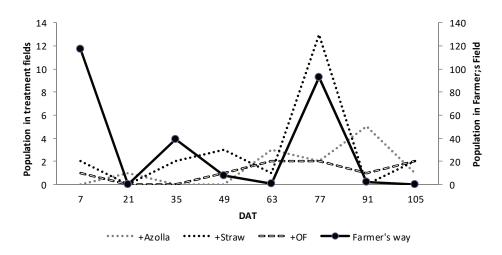

FIGURE 2. Population Dynamic of Opius Sp., Cotesia sp. and Goniozus sp. during Observation

Result of Analysis of Variance on a Diversity Component

The variances of each α diversity measurement in every observation were compared. The measurement contains four components, which are heterogeneity index, dominance index, richness, and evenness. There are fluctuations of each component in every observation, but in the average, they all showed a significant difference (Table 2).

| TABLE 2. Analysis of variance on detrivore data | | | | | | | | |
|---|--------------------------|------------------|----------|----------|--|--|--|--|
| Anova | Indicator of α diversity | | | | | | | |
| Anova f _{0.05} (4,8) 2.94 | Heterogeneity index | Domination index | Richness | Evenness | | | | |
| Detritus | 12.59* | 3.96* | 5.37* | 6.16* | | | | |
| Natural enemy | 8.28* | 10.08* | 3.43* | 2.44 | | | | |

Remark: The mark (*) showed significant differences as the value of F criteria is higher than F statistic

Heterogeneity index, richness, and evenness in the farmer's field are the lowest (Table 3). Higher heterogeneity index explains that a habitat contains a wider variety of species which all species has an equal abundance. Heterogeneity index will show the highest value if only two factors accomplished. The first factor is the higher number of species which is indices by species richness. The second is the higher evenness. Meanwhile, evenness measure observed the pattern in a hypothetical assemblage [16]. Its value varies from 0 to 1. If the value approaches 1 then all species are equally abundant. On the contrary, the lower value shows a "broken stick" distribution. It happens when certain species has a high population and the other rare species. In other words, there were a dominant

species within the habitat. In so, the value of the dominance index will inversely compare to the three others. It showed in Table 3 that added biomass has increased α diversity of detritus population data. +OF has the highest improvement to the value of the heterogeneity index.

| Tuesday and Field | | Average | | | | | | | |
|------------------------|-----------------|---------|---------------------|----|-----------------|----|------------------|---|--|
| Treatment Field | heterogeneity | | dominance | | richness | | evenness | | |
| + Azolla | 1.53 ± 0.11 | bc | $0.31{\pm}0.01$ | а | 1.83 ± 0.12 | b | 0.70 ± 0.02 | b | |
| + Straw | 1.26 ± 0.06 | b | $0.42 \pm \! 0.007$ | а | 1.62 ± 0.22 | ab | 0.62 ± 0.005 | b | |
| + OF | 1.66 ± 0.01 | с | $0.27{\pm}0.003$ | ab | 1.99 ± 0.16 | b | 0.75 ± 0.01 | b | |
| farmer's way | $0.80{\pm}0.20$ | а | $0.50{\pm}0.06$ | b | 1.20 ± 0.19 | а | 0.45 ± 0.05 | а | |

TABLE 3. Differences of α diversity indicator on detrivore population between fields

Remark: *) the notation showed significant differences based on LSD's test

There is clear evidence that adding biomass could enhance detritus species. Not only its population, but also its heterogeneity index, richness, and evenness. Collembolan found as the most common order of detritus. Its densities vary from 814 .m⁻³ in +Straw, 1,663.m⁻³ in +Azolla to 1,910.m⁻³ in +OF. Meanwhile in Farmer's way was 672.m⁻³. Collembolan feeds on decaying matters and associated micro-flora. The micro-flora especially fungi (*Trichoderma* sp. and *Aspergillus* sp.) in treatment fields has increased (Table 4). It could be determined that a sufficient food source is present. Without the availability of organic matter, collembolan would potentially become pest [17].

| TABLE 4. The population of dominant fungi in Propagul g/m | | | | | | |
|--|--------|---------|-------|--------------|--|--|
| Soil dominant microflora | +Straw | +Azolla | +OF | Farmer's way | | |
| Tricogramma sp. | 52,000 | 2,300 | 43000 | 1,100 | | |
| Aspergillus sp. | 91,000 | 3,600 | 88000 | 1,200 | | |

In fact, adding biomass not only provides more fungus propagules as micro-flora but also enhance protozoa. In the soil community, protozoa have a role as a major predator of bacteria. So it could regulate plant diseases caused by bacteria [18]. *Lumbricus* sp. was used as an indicator species for the presence of protozoa [19]. It was found that the *Lumbricus* sp. population increase more three times in +straw and +o.f compare to those in farmer's site (177. m⁻³). The highest population is in +Azolla field (708. m⁻³).

Even though, added biomass did not show a clear effect in the individual number of the natural enemy but a contrast occurred if the data converse to α diversity component. There was a significant effect of added biomass to heterogeneity index, dominance index, and species richness. All the treatments field has a higher index, especially in +OF field (Table 5).

| Field | Average | | | | | | | |
|--------------|-----------------|-----|------------------|---|-----------------|----|------------------|---|
| rield | Heterogene | ity | Dominance | | Richness | | Evenness | |
| + Azolla | 1.99 ± 0.11 | b | $0.17{\pm}0.003$ | а | 2.93±0.59 | ab | $0.92{\pm}0.001$ | а |
| + Straw | $2.00{\pm}0.07$ | b | 0.17 ± 0.002 | а | 2.73 ± 0.60 | ab | 0.89 ± 0.002 | а |
| + OF | 2.11 ± 0.07 | b | 0.15 ± 0.002 | а | 3.18 ± 0.55 | b | 0.91 ± 0.003 | а |
| Farmer's way | 1.30 ± 0.28 | а | 0.46 ± 0.06 | b | 2.09 ± 0.25 | а | 0.68±0.16 | а |

TABLE 5. Differences of α diversity indicator on natural enemies population between fields

Remarks: *) the notation showed significant differences based on LSD test

Opius sp. population outbreak may lead to the abundance of rice flies as the main host in the farmer's field. Or there was a temporary niche because of its sporadic pattern. In spite, the natural enemy diversity components improve in treatments fields. The proportion between detritus and natural enemies are better in every treatment field compared to farmer's way. It shows that a lower layer of the food web has a bigger population. It will decrease the opportunity of intra-guild predation or intra-guild parasite in the treatment fields [20].

Results of β **diversity**

The dissimilarity between habitat, that is tested by ANOVA (Table 2 and 3), showed the rising of heterogeneity index as results of the more abundance equality. Another way, there is evidence that some habitat has a shared

species with others. Measurement of a β diversity index is needed to ensure whether two habitats have more or fewer species overlap. β diversity becomes a reflection that a biotic change has occurred.

There are some methods to determine β diversity, one of them is Whittaker formula [16]. It extends the difference between habitat by comparing the number of species found in each site relatively into a total number of species that occurs in both areas or named as shared species. The similarity comes if a more of shared species found on both sites.

| LE U . Result of p DI | versity wiedsuiv | is according to v | VIIIttakei 310II |
|------------------------------|------------------|-------------------|------------------|
| | + Azolla | +Straw | +OF |
| Farmer ways | 0.65 | 0.42 | 0.61 |
| + Azolla | | 0.56 | 0.50 |
| + Straw | | | 0.55 |

TABLE 6. Result of β Diversity Measures according to Whittaker's Formula

Remarks: the lower β diversity indicates similarity between 2 sites according to the larger number of its complementary species.

According to Whittaker formula results (Table 6), the straw application has the most similarity habitat with farmer's way. It shows that straw has a lower effect on the species diversity. It also means that straw and farmer's way have the highest complementary species. Meanwhile, Azolla application brings the biggest impact on species changing if it compares to farmer's way. The numbers of complementary species between sites are drawn below in Fig. 3.

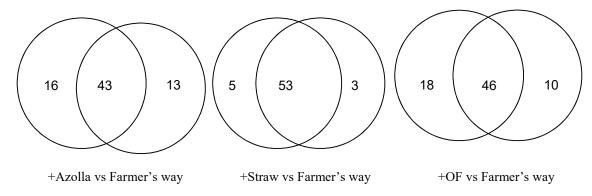

FIGURE 3. Complementary species between 2 sites

 β diversity measurement shows that differences between site also determined by the magnitude of faunal turnover observed [21]. The more size of magnitude means the less number of shared species. It only 33 shared species of 89 morpho-species in all four habitats (37%). The result of a pair comparing on every site according to species richness sequence (Fig. 4) was used to explain the turnover of species that occurred between treatment sites. It shows that each biomass has a different effect on species turnover. For example, we see that in +straw vs +azolla the number of species has a slight difference. In the same time, it has the highest value of β . It means there were a less shared species between two sites. It also defines that some dominant morpho-species are specialized to particular habitats.

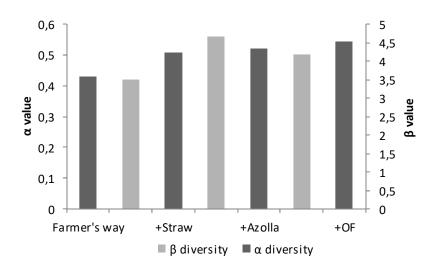

FIGURE 4. Changes in α and β Diversity with biomass added

Assessment of Environment Health

Adding biomass is either Azolla, straw or organic fertilizer tends to increase species richness by providing niche conservation [22]. An improvement in species richness followed decreasing dominance promising a better agroecosystem. It could be used as an indicator of sufficient population of natural enemies occurred. And so the pest control mechanism available as ecological services.

A better diversity of soil fauna in the treatment field will enhance carbon-nitrogen cycling and decomposition of a various compound into nutrient [22]. There is also an improvement of soil chemical compound (shown in Table 7). It proves that a promising nutrient cycle also occurs, as one of the ecological services.

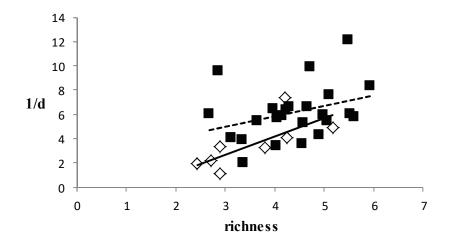

FIGURE 5. The Diversity Comparison between 8 observations in farmer's sites (open diamond) with the 24 observation on treatments sites. Solid regression depicts farmers site data series, the broken line for treatment. The farmer's site could be distinguished from treatment site of equivalent richness (ANCOVA F8,24 =8.273 P=0.001).

| Soil chemical compound | +Straw | +Azolla | +OF | Farmer's way |
|------------------------|--------|---------|------|--------------|
| C-organic | 2.26 | 2.29 | 2.16 | 1.37 |
| N-total | 0.26 | 0.3 | 0.24 | 0.16 |
| Р | 51.43 | 12.83 | 12.1 | 18.13 |
| Κ | 0.83 | 15.93 | 0.55 | 0.26 |
| Organic matter | 3.9 | 3.96 | 3.73 | 2.37 |

TABLE 7. Comparison of Soil Chemical Compound between Treatment and Farmer's Way

SUMMARY

Adding certain biomass in an early stage of the agricultural system will enhance both of detrivore's population and diversity. It also enhances natural enemy's diversity and so, increases the possibility to gain pest control services from agro-ecosystem. It shows that adding organic fertilizer has the biggest impact. Furthermore, adding biomass could enhance agro-ecosystem health according to richness-dominance covariance. Biomass application regularly in every agricultural cycle will provide ecological services that it is important forther sustainability of the rice field productivity.
